HOW WE "SEE"

IN 3D

Atomic Gas

Figure 10. Riegel–Crutcher cloud (Section 6) in H I absorption (left) and RHT backprojection (right). Overlaid pseudovectors represent polarization angle measurements from the Heiles (2000) compilation. In the left panel, the intensity scale is linear from -20 K (white) to -120 K (black).

(A color version of this figure is available in the online journal.)

The Milky Way in Molecular Clouds

The Milky Way and its nearest neighbors, the Andromeda galaxy (M31) and the Large Magellanic Cloud (LMC), are shown in the 100 GHz line of carbon monoxide (CO), the best tracer of interstellar molecular clouds. These clouds, the factories of new stars, are shown in almost every direction of molecular hydrogen and atomic carbon, both nearly invisible to detect.

In the top map the colors, from dark blue (coldest) to white (warmest), represent the CO line intensity summed over all radial velocities, a measure of the total amount of molecular gas along the line of sight. The velocity-resolved horizontal strip at the center of the map is projected to the large number of molecular clouds in the nearest spiral arms of the Galaxy, which dominates the map. Molecular clouds are shown in the map, labeled with their names, along with their Galactic longitude, latitude, and distance from the Galactic center. The LMC and M31 are also shown in CO, but their intensity has been scaled up by factors of 2 and 10, respectively. A scale bar is on the left.

The bottom map shows the distribution of the CO-emitting nuclear star clouds in radial velocity-resolved information lacking in conventional surveys. Most of the colors represent CO line intensity summed across a $\pm 1^\circ$ strip of Galactic latitude centered on the Galactic plane. Molecular clouds at higher latitudes (near the LMC and M31) are therefore excluded. The observed radial velocity results mainly from the differential motions of the Galaxy, except near the Galactic center, where a poorly understood mixture of motions give rise to the 200 km/s spread. A scale bar is on the right.

This paper is an update of one published ten years ago which presented the first complete survey of the Milky Way in CO first rotation as well as Dame (1983, Star of Chicago, N. 22). Since well before completion of the survey, done at an effective angular resolution of 0.7° , the same has 12 more telescopes in Cambridge, Mass., and in Ohio State, Ohio, have been mapping the Galaxy and its nearest neighbors at several times higher angular resolution—between 0.7 and 0.2 arcmin on half the main—now 20 to 30 times higher resolution per solid angle. These improvements have now resulted in the very near to the entire Galactic plane over a $4^\circ \times 9^\circ$ strip of latitude, as well as many local clouds at higher latitudes. The maps allow us to see that 20,000 new galaxies the original CO map revealed in some high-latitude regions (e.g., Triangulum) where submillimeter observations do not penetrate.

Though half of the new data have already been published as separate surveys of particular clouds or regions (see list at right), and Dame (1993) have formed the basis for 13 Ph.D. dissertations. The balance was obtained in the past few years in new large-scale surveys of the first and second Galactic quadrants.

This paper was supported by a generous grant from the Adelson-Belden Endowment of the Smithsonian Institution.

ABSTRACT

The all-Galaxy CO survey of Dame et al. is by far the most uniform, large-scale Galactic CO survey. Using a dendrogram-based decomposition of this survey, we present a catalog of 1064 massive molecular clouds throughout the Galactic plane. This catalog contains 2.5×10^8 solar masses, or $25^{+10.7}_{-5.8}$ % of the Milky Way’s estimated H_2 mass. We track clouds in some spiral arms through multiple quadrants. The power index of Larson’s first law, the size–linewidth relation, is consistent with 0.5 in all regions—possibly due to an observational bias—but clouds in the inner Galaxy systematically have significantly ($\sim 30\%$) higher linewidths at a given size, indicating that their linewidths are set in part by the Galactic environment. The mass functions of clouds in the inner Galaxy versus the outer Galaxy are both qualitatively and quantitatively distinct. The inner Galaxy mass spectrum is best described by a truncated power law with a power index of $\gamma = -1.6 \pm 0.1$ and an upper truncation mass of $M_0 = (1.0 \pm 0.2) \times 10^7 M_\odot$, while the outer Galaxy mass spectrum is better described by a non-truncating power law with $\gamma = -2.2 \pm 0.1$ and an upper mass of $M_0 = (1.5 \pm 0.5) \times 10^6 M_\odot$, indicating that the inner Galaxy is able to form and host substantially more massive GMCs than the outer Galaxy. Additionally, we have simulated how the Milky Way would appear in CO from extragalactic perspectives, for comparison with CO maps of other galaxies.

catherine.zucker@cfa.harvard.edu

Nessie is a "Bone" of the Milky Way

1 The infrared dark cloud "Nessie" seen in extinction. Its length (160+ pc) and aspect ratio (>300:1) suggests its formation is due to the global spiral potential of the Galaxy.

2 Nessie lies within 3 pc of the physical Galactic midplane (dashed colored line), at $d=3.1$ kpc

3

Nessie's velocity gradient exactly matches the global-log spiral fit to the Scutum Centaurus Arm in p-v space

And it may have friends!

4 Milky Way Bones: Ultra-dense, high aspect ratio Nessie analogs that may form the "Skeleton" of the Milky Way. Analogs must satisfy quantitative Bone criteria (Zucker+2015)

2.3. Establishing "Bone" Criteria
After narrowing down our list to 10 filaments with kinematic structure consistent with existing spiral arm models, we develop a set of criteria for an object to be called a "bone":
1. Largely continuous mid-infrared extinction feature
2. Parallel to the Galactic plane, to within 30"
3. Within 20pc of the physical Galactic midplane, assuming a flat galaxy
4. Within 10km s⁻¹ of the global-log spiral fit to any Milky Way arm
5. No other objects in velocity (of more than 3 km s⁻¹ per 10pc) within extinction feature
6. Projected aspect ratio >50:1

5 Giant Molecular Filaments: 70+ pc lower density filaments traced mainly by ¹³CO, with typical aspect ratios between 5:1-10:1 (Ragan+2014, Abreu-Vicente+2016)

6 Large-Scale Herschel Filaments: Dense, cold filaments (aspect ratios >>10) chosen through visual inspection of HI-GAL images. Confirmed velocity contiguous through ¹³CO GRS data (Wang+2015)

7

MST Bones: Filaments created by connecting dense BGPS N₂H+/HCO+ sources in p-p-v space using Minimum Spanning Tree algorithm. Must also satisfy additional Bone criteria based on Zucker+2015 criteria (Wang+2016)

But they have different properties and utility in tracing spiral structure

8 Size Scale Comparison of Large-Scale Filament Catalogs: Herschel column density map with filament outlines overlaid

10

Systematic offsets in column density (top left), temperature (top right), scale height (bottom left) and position angle (bottom right) among different classes

ABSTRACT

After studying how line width depends on spatial scale in low-mass star-forming regions, we propose that “dense cores” (Myers & Benson 1983) represent an inner scale of a self-similar process that characterizes larger scale molecular clouds.

FIG. 10.—An illustration of the transition to coherence. Color and shading schematically represent velocity and density in this figure. On large scales, material (labeled chaff) is distributed in a self-similar fashion, and its filling factor is low. On scales smaller than some fiducial radius, the filling factor of gas increases substantially, and a coherent dense core, which is not self-similar, is formed. Due to limitations in the authors' drawing ability, the figure emphasizes a particular size scale in the chaff, which should actually exhibit self-similar structure on all scales ranging from the size of an entire molecular cloud complex down to a coherent core.

Figure 1. Left panel: integrated intensity map of B5 in NH_3 (1,1) obtained with GBT. Gray contours show the 0.15 and 0.3 K km s^{-1} level in NH_3 (1,1) integrated intensity. The orange contours show the region in the GBT data where the non-thermal velocity dispersion is subsonic. The young star, B5-IRS1, is shown by the star in both panels. The outflow direction is shown by the arrows. The blue contour shows the area observed with the EVLA and the red box shows the area shown in the right panel. Right panel: integrated intensity map of B5 in NH_3 (1,1) obtained combining the EVLA and GBT data. Black contour shows the $50 \text{ mJy beam}^{-1} \text{ km s}^{-1}$ level in NH_3 (1,1) integrated intensity. The yellow box shows the region used in Figure 4. The northern starless condensation is shown by the dashed circle.

AND SUB-SUB STRUCTURE

WE NOW ALSO KNOW THAT B5 IS (RAPIDLY) FORMING A BOUND CLUSTER

The formation of a quadruple star system with wide separation

Jaime E. Pineda¹, Stella S. R. Offner^{2,3}, Richard J. Parker⁴, Héctor G. Arce⁵, Alyssa A. Goodman⁶, Paola Caselli⁷, Gary A. Fuller⁸, Tyler L. Bourke^{9,10} & Stuart A. Corder^{11,12}

The initial multiplicity of stellar systems is highly uncertain. A number of mechanisms have been proposed to explain the origin of binary and multiple star systems, including core fragmentation, disk fragmentation and stellar capture^{1–3}. Observations show that protostellar and pre-main-sequence multiplicity is higher than the multiplicity found in field stars^{4–7}, which suggests that dynamical interactions occur early, splitting up multiple systems and modifying the initial stellar separations^{8,9}. Without direct, high-resolution observations of forming systems, however, it is difficult to determine the true initial multiplicity and the dominant binary formation mechanism. Here we report observations of a wide-separation (greater than 1,000 astronomical units) quadruple system composed of a young protostar and three gravitationally bound dense gas condensations. These condensations are the result of fragmentation of dense gas filaments, and each condensation is expected to form a star on a timescale of 40,000 years. We determine that the closest pair will form a bound binary, while the quadruple stellar system itself is bound but unstable on timescales of 500,000 years (comparable to the lifetime of the embedded protostellar phase¹⁰). These observations suggest that filament fragmentation on length scales of about 5,000 astronomical units offers a viable pathway to the formation of multiple systems.

Detailed knowledge of the underlying distribution of dense gas is the key to determining which structures will go on to form stars. Here we identify the dense gas structures that are most likely to form stars using the dendrogram technique²¹. Dendrogram analysis is a hierarchical structure decomposition that uses isocontours to identify individual features, while also determining where these contours merge with adjacent structures to create a new parental structure. We refer to the smallest scale (and brightest) structures in the dendrogram as condensations. These are the most likely places for an individual star to form. Figure 1a shows the B5 region as seen in dense gas (number density of H_2 , $n_{\text{H}_2} \approx 10^4 \text{ cm}^{-3}$), with the protostar and the identified gas condensations shown by a star and circles, respectively. The mass of the well-known protostar B5-IRS1 is 0.1 solar masses (M_{Jup} ; ref. 22), while the masses of condensations B5-Cond1, B5-Cond2 and B5-Cond3 are $0.36 \pm 0.09 M_{\text{Jup}}$, $0.26 \pm 0.12 M_{\text{Jup}}$ and $0.30 \pm 0.13 M_{\text{Jup}}$, respectively. Uncertainty in these masses is dominated by the uncertainty in the temperature used to convert measured fluxes to masses. The radii of the three condensations are respectively 2,800 AU, 2,300 AU and 2,500 AU, while the projected separations between the same three condensations and the protostar are 3,300 AU, 5,100 AU and 11,400 AU (see Methods). The half-mass radii of the condensations are about half the condensation radii. This, combined with

isothermal,
 hydrostatic filaments,
 not turbulent ones?

SOME PLACES ARE SPECIAL

What are “special” places in ISM & how long do they last?

–galactic plane, **Bones**

–filaments’ influence may last into cores—how long, and when, simulators?

How do “influences” change what is special?

–magnetic fields, feedback, “collisions,” but when, how & where, simulators?
